ABSTRACT Antiretroviral therapy (ART) inhibits HIV-1 replication, but the virus persists in latently infected resting memory CD4+ T cells susceptible to viral reactivation. The virus-encoded early gene product Tat activates transcription of the viral genome and promotes exponential viral production. Here we show that the Tat inhibitor didehydro-cortistatin A (dCA), unlike other antiretrovirals, reduces residual levels of viral transcription in several models of HIV latency, breaks the Tat-mediated transcriptional feedback loop, and establishes a nearly permanent state of latency, which greatly diminishes the capacity for virus reactivation. Importantly, treatment with dCA induces inactivation of viral transcription even after its removal, suggesting that the HIV promoter is epigenetically repressed. Critically, dCA inhibits viral reactivation upon CD3/CD28 or prostratin stimulation of latently infected CD4+ T cells from HIV-infected subjects receiving suppressive ART. Our results suggest that inclusion of a Tat inhibitor in current ART regimens may contribute to a functional HIV-1 cure by reducing low-level viremia and preventing viral reactivation from latent reservoirs.

IMPORTANCE Antiretroviral therapy (ART) reduces HIV-1 replication to very low levels, but the virus persists in latently infected memory CD4+ T cells, representing a long-lasting source of resurgent virus upon ART interruption. Based on the mode of action of didehydro-cortistatin A (dCA), a Tat-dependent transcription inhibitor, our work highlights an alternative approach to current HIV-1 eradication strategies to decrease the latent reservoir. In our model, dCA blocks the Tat feedback loop initiated after low-level basal reactivation, blocking transcriptional elongation and hence viral production from latently infected cells. Therefore, dCA combined with ART would be aimed at delaying or halting ongoing viral replication, reactivation, and replenishment of the latent viral reservoir. Thus, the latent pool of cells in an infected individual would be stabilized, and death of the long-lived infected memory T cells would result in a continuous decay of this pool over time, possibly culminating in the long-awaited sterilizing cure.

Antiretroviral therapy (ART) has significantly improved the health and quality of life of many individuals infected with HIV-1. However, ART fails to permanently eradicate the virus. Stable reservoirs composed of latently infected resting memory CD4+ T cells harbor an integrated form of the HIV genome that, in the absence of ART, can reignite active replication (1–4). The long half-life of latently infected cells appears to be mainly responsible for HIV persistence in individuals receiving ART (5, 6). In addition to these latently infected cells, HIV may still persist through ongoing viral replication in subjects on suppressive ART (7–9), although this mechanism of viral persistence remains controversial (10, 11). Residual viremia is thought to be a major contributor to inflammation and other HIV-associated complications, leading to cardiovascular and neurological diseases (12). Unfortunately, ART intensification does not seem to reduce the size of the viral reservoir nor inhibit residual viremia (13, 14).

The early virus-encoded gene product Tat is required for robust transcription of the integrated viral genome by RNA polymerase II (RNAP II) (15, 16). Tat binds the 5′ terminal region of the HIV mRNA stem-bulge-loop structure transactivation response element (TAR) and recruits the positive transcription elongation factor B (P-TEFb), composed of cyclin T1 and cyclin-dependent kinase 9 (CDK9), to promote transcriptional elongation from the viral promoter (5′-long terminal repeat [5′-LTR]) (17–19).

In resting CD4+ T cells, HIV-1 is maintained in a latent state by several mechanisms. These include low levels of Tat (20, 21) or active P-TEFb (22), the exclusion of cellular transcription factors such as nuclear factor κB (NF-κB) and nuclear factor of activated...
production of viral particles (45). There is evidence that latently loop that drives exponential increase in viral transcription and the homologs. Moreover, direct inhibition of Tat blocks the feedback it is expressed early during virus replication and it has no cellular reductions in both acutely and chronically infected cells. In primary cdCA represses residual HIV-1 transcription and production in cellular models of HIV latency. None of the existing cell line models accurately reflects the HIV latency observed in quiescent CD4+ T cells from HIV-infected individuals (55). This is in part because latency is established by a combination of events, including variation in the levels of transcription factors and dNTPs, as well as the location and sense of proviral integration, among others. This multitude of factors may vary between latently infected CD4+ T cells, resulting in different residual viral transcriptional activities. Moreover, cell lines used in vitro are not quiescent and are often transformed to maintain their immortality. Notably, HIV latency models derived from primary cells using clonal tissue culture-adapted virus have shown largely divergent results upon stimulation (55), demonstrating the difficulty of recapitulating latency in vitro. Nonetheless, the available in vitro models have proven useful to understand several aspects of HIV latency. Therefore, we next investigated cdCA’s impact on the residual levels of
HIV transcription commonly detected in several latently infected cell lines and whether dCA could achieve complete transcriptional silencing.

We first tested the effect of dCA in a population of HeLa-CD4 cells latently infected with the HIV-1 isolate NL4-3, a cell population which we developed in the laboratory and that is characterized by very low levels of virus production. We treated these cells for a period of 239 days with 100 nM dCA or dimethyl sulfoxide (DMSO) (Fig. 2A, left panel). Residual levels of HIV-1 p24 antigen production were monitored in the supernatant using a sandwich ELISA. In the presence of dCA, we observed a continuous reduction in the levels of p24 release to below the limit of detection of the assay (3.1 pg/ml) by day 82. dCA, but not other ARVs (200 nM lamivudine, 200 nM raltegravir, and 100 nM efavirenz), reduced residual levels of viral production. Viral production remained below the limit of detection for over 4 months (Fig. 2A, left panel). Of note, no residual traces of dCA were observed by liquid chromatography-mass spectrometry in HeLa-CD4 cell extracts passed 3 or 11 times upon drug withdrawal (see Fig. S1C in the supplemental material). Altogether, these results suggest that the long-lasting inhibitory effects of dCA on virus production are likely due to epigenetic transcriptional repression, as no viral transcripts were produced after removal of the drug.

To verify that long-term treatment with dCA had not simply positively selected for uninfected HeLa-CD4 cells, we determined the number of integrated proviruses by Alu-PCR followed by qPCR at days 0, 129, 178, and 194 of culture (see Fig. S1D in the supplemental material). Interestingly, we observed a higher number of integrated proviruses in dCA-treated latent cells than in DMSO-treated controls. This result may be explained by negative selection of cells with multiple viral integration events. In contrast, in dCA-treated cells, the absence of proviral expression would bypass this counterselection and allow survival of cells with multiple integrated proviruses. Nevertheless, these results confirmed that dCA-treated cells contain integrated provirus, and the lack of virus production is due to a loss of transcription and not to a loss of infected cells.

The drastic reductions in virus production and viral transcription were also confirmed in well-characterized cell line models of latency, such as the promyelocytic OM-10.1 (59) and the J-Lat T-lymphocytic (60) cell lines (Fig. 2B, C, and D). OM-10.1 cells carry a competent provirus, while J-Lat cells harbor an HIV-1 genome with a frameshift mutation in env that renders them tran-
dCA inhibits residual transcription in HIV-1 latently infected cell line models. (A) dCA inhibits NL4-3 virus expression to undetectable levels in HeLa-CD4 cells (left panel). Latently infected HeLa-CD4 cells were treated with DMSO control or dCA for 239 days (100 nM dCA used from 0 to 118 days and then at 10 nM afterward). dCA treatment was stopped at day 24 (TS1) and day 105 (TS2). TS, treatment stop. Capsid p24 in the supernatants was assayed in an ELISA (detection limit, 3.1 pg/ml). Data are representative of two independent experiments (right panel). For analysis of viral mRNA expression, cDNAs from total RNA extracted at day 239 were quantified by RT-qPCR using primers to the Vpr region. Results were normalized as number of viral cDNAs from total RNA extracted at day 239 were quantified by RT-qPCR to measure transcription initiation (nuclease 0 [Nuc-0], promoter [Pro], and Nuc-1 amplicons) and elongation (Vpr amplicon) (Fig. 3). As controls for RNAP II recruitment, we used tumor necrosis factor alpha (TNF-α) to activate the vehicle cells and α-amanitin to inhibit RNAP II activity (Fig. 3B and C). Recruitment of RNAP II during transcription initiation was reduced 2-fold upon dCA treatment, while the occupancy of RNAP II on the GAPDH promoter or open reading frame (ORF) was unchanged by dCA (Fig. 3B and C). Transcriptional elongation (vpr) was reduced by 80% in dCA-treated cells, demonstrating that blocking Tat activity further reduces transcription in latent cells already expressing few viral transcripts (Fig. 3B). In this particular latently infected model, TNF-α activation induced a 2-fold increase in the levels of p24 production (see Fig. S3 in the supplemental material), which was paralleled by a similar increase in RNAP II recruitment at the LTR, as determined by ChIP (Fig. 3B). As a control, we used the RNAP II inhibitor α-amanitin and, as expected, the drug inhibited RNAP II recruitment at all positions (Fig. 3B and C). Collectively, these results demonstrated that dCA represses residual levels of HIV transcription and viral production in latently infected cells by inhibiting the recruitment of RNAP II.

CpG hypermethylation does not contribute to dCA-induced latency. Several CpG islands have been identified within the HIV transcriptionally competent but replication incompetent. Similar to latently infected HeLa-CD4 cells, treatment of OM-10.1 cells for 226 days with 10 or 100 nM dCA in the presence of ARVs reduced p24 production to close to the assay’s limit of detection (Fig. 2B, left panel). Consistently, viral mRNA levels were reduced by 98% at day 197 (Fig. 2B, right panel). As expected, in the OM-10.1 model, the number of integrated proviruses was not affected by the long-term treatment with dCA combined with ARVs (see Fig. S2A in the supplemental material). In J-Lat clones 6.3 and 10.6, dCA treatment resulted in similar effects as in HeLa-CD4 and OM-10.1 cells, as demonstrated by the reduction in p24 and viral mRNA production by 10 nM dCA during the shorter 18-day treatment period (Fig. 2C and D). dCA was not toxic or cytostatic in any of the tested cell lines (see Fig. S2B and C). Altogether, our results demonstrated the ability of the Tat inhibitor dCA to induce transcriptional silencing in several cell line models of HIV latency.

**dCA treatment results in loss of RNAP II recruitment to the HIV promoter.** To confirm that transcriptional inhibition was at the root of the dCA-mediated block of viral mRNA production in HeLa-CD4 cells, we performed chromatin immunoprecipitation (ChIP) to RNAP II followed by RT-qPCR to measure transcription initiation (nuclease 0 [Nuc-0], promoter [Pro], and Nuc-1 amplicons) and elongation (Vpr amplicon) (Fig. 3). As controls for RNAP II recruitment, we used tumor necrosis factor alpha (TNF-α) to activate the vehicle cells and α-amanitin to inhibit RNAP II activity (Fig. 3B and C). Recruitment of RNAP II during transcription initiation was reduced 2-fold upon dCA treatment, while the occupancy of RNAP II on the GAPDH promoter or open reading frame (ORF) was unchanged by dCA (Fig. 3B and C). Transcriptional elongation (vpr) was reduced by 80% in dCA-treated cells, demonstrating that blocking Tat activity further reduces transcription in latent cells already expressing few viral transcripts (Fig. 3B). In this particular latently infected model, TNF-α activation induced a 2-fold increase in the levels of p24 production (see Fig. S3 in the supplemental material), which was paralleled by a similar increase in RNAP II recruitment at the LTR, as determined by ChIP (Fig. 3B). As a control, we used the RNAP II inhibitor α-amanitin and, as expected, the drug inhibited RNAP II recruitment at all positions (Fig. 3B and C). Collectively, these results demonstrated that dCA represses residual levels of HIV transcription and viral production in latently infected cells by inhibiting the recruitment of RNAP II.

CpG hypermethylation does not contribute to dCA-induced latency. Several CpG islands have been identified within the HIV LTR, as determined by ChIP (Fig. 3). As controls for RNAP II recruitment, we used tumor necrosis factor alpha (TNF-α) to activate the vehicle cells and α-amanitin to inhibit RNAP II activity (Fig. 3B and C). Recruitment of RNAP II during transcription initiation was reduced 2-fold upon dCA treatment, while the occupancy of RNAP II on the GAPDH promoter or open reading frame (ORF) was unchanged by dCA (Fig. 3B and C). Transcriptional elongation (vpr) was reduced by 80% in dCA-treated cells, demonstrating that blocking Tat activity further reduces transcription in latent cells already expressing few viral transcripts (Fig. 3B). In this particular latently infected model, TNF-α activation induced a 2-fold increase in the levels of p24 production (see Fig. S3 in the supplemental material), which was paralleled by a similar increase in RNAP II recruitment at the LTR, as determined by ChIP (Fig. 3B). As a control, we used the RNAP II inhibitor α-amanitin and, as expected, the drug inhibited RNAP II recruitment at all positions (Fig. 3B and C). Collectively, these results demonstrated that dCA represses residual levels of HIV transcription and viral production in latently infected cells by inhibiting the recruitment of RNAP II.

CpG hypermethylation does not contribute to dCA-induced latency. Several CpG islands have been identified within the HIV LTR, as determined by ChIP (Fig. 3). As controls for RNAP II recruitment, we used tumor necrosis factor alpha (TNF-α) to activate the vehicle cells and α-amanitin to inhibit RNAP II activity (Fig. 3B and C). Recruitment of RNAP II during transcription initiation was reduced 2-fold upon dCA treatment, while the occupancy of RNAP II on the GAPDH promoter or open reading frame (ORF) was unchanged by dCA (Fig. 3B and C). Transcriptional elongation (vpr) was reduced by 80% in dCA-treated cells, demonstrating that blocking Tat activity further reduces transcription in latent cells already expressing few viral transcripts (Fig. 3B). In this particular latently infected model, TNF-α activation induced a 2-fold increase in the levels of p24 production (see Fig. S3 in the supplemental material), which was paralleled by a similar increase in RNAP II recruitment at the LTR, as determined by ChIP (Fig. 3B). As a control, we used the RNAP II inhibitor α-amanitin and, as expected, the drug inhibited RNAP II recruitment at all positions (Fig. 3B and C). Collectively, these results demonstrated that dCA represses residual levels of HIV transcription and viral production in latently infected cells by inhibiting the recruitment of RNAP II.

**Figure Legend Continued**

Data are representative of four independent experiments with treatment of cells ranging from 42 to 226 days (right panel). For analysis of viral mRNA expression in dCA-treated OM-10.1 cells, cDNAs from total RNA (day 197) were quantified, normalized, and are reported as described for panel A using primers to the Gag-Pol region. Data are representative of three analyses at days 102, 163, and 197. (C and D) Effects of dCA on J-Lat 6.3 and 10.6 clones (left panels). Cells were split and treated on average every 3 days with or without 10 nM dCA. Capsid production was quantified via a p24 ELISA, and results for the DMSO controls were set to 100%. Data are reported as means ± SD of two or three independent experiments, respectively. Significant effects of dCA (****, P < 0.0001) and time (****, P < 0.0001) were determined by a two-way repeated-measures ANOVA with Bonferroni correction post hoc (n = 3 per group) (right panels). DCA inhibited viral transcription in J-Lat clones. Viral mRNA levels (day 9) were quantified, normalized, and are reported as described for panel A, using Gag-Pol primers. Data are representative of two independent experiments.

regulated kinases 1 and 2 (ERK1/2) were phosphorylated equally well under the two conditions (see Fig. S5B).

To demonstrate that the integrated provirus in HeLa-CD4 cells treated long term with dCA were transcriptionally competent but incapable of reactivation due to the lack of Tat activity mediated by dCA, a plasmid harboring the Tat gene or the corresponding empty vector (Fig. 4B) was transfected into control or long-term-treated dCA cells. In control cells, the plasmid produced Tat-reactivated viral production well above the normal basal level (approximately 2 logs). When the Tat-carrying plasmid was transfected in long-term-dCA-treated cells, in the presence or absence of dCA we observed a similar robust level of viral reactivation in both cases, indicating that latent provirus expression can be rescued by large amounts of Tat. The presence of the Tat inhibitor only decreased by 2-fold the reactivation, suggesting that an excess of the overexpressed Tat overrides dCA function. Unexpectedly, within 17 days viral production from the long-term dCA-treated cells returned to below the limit of viral detection even in the absence of dCA, suggesting that the mechanisms involved in the maintenance of dCA-mediated latency are long lasting and not easily circumvented. To determine whether the HIV NL4-3 produced in response to Tat stimulation remained replication competent and that dCA-mediated latency was not simply the result of the accumulation of impairing mutations over time, we used the supernatants from both DMSO- and dCA-treated cells activated by Tat and cultured the released viruses. Viruses produced from these newly infected HeLa-CD4 cells replicated in vitro and could be inhibited by 10 nM dCA (see Fig. S5C in the supplemental material). Proviral DNA from the DMSO- and dCA-treated samples (from day 178) were sequenced and aligned to the HIV-1 NL4-3 reference sequence and this revealed only three unique mutations in the dCA-induced latent virus sequence (see Fig. S5D). This limited mutation profile is characteristic of chronically infected cells, in which rates of replication are low. Two of these mutations, one in a noncoding region (G771A) and one encoding a K314R change, are not known to impair HIV replication. A third mutation, S173A in the Gag region, is rare (5% of subtype B virus) and known to be compensatory for Gag-specific CD8+ T-lymphocyte response escape mutant R264K (67).

Together, our results demonstrated that the potent PMA-ions stimulus was not sufficient to reactivate viral production in HeLa-CD4 cells treated with dCA, but that viral production could be rescued by exogenous Tat production. Furthermore, we did not identify mutations that would impair the fitness of the latent virus, indicating that transcriptional inhibition established by long-term treatment with dCA results from loss of Tat activity and not from positive selection of proviruses incompetent for replication.

Both TNF-α and the PKC agonist prostratin trigger the NF-κB pathway and activate HIV transcription (68, 69). HDAC inhibitors, such as suberoylanilide hydroxamic acid (SAHA), are known activators of HIV production in latently infected cell lines and primary cells (70). To substantiate the results found with HeLa-CD4 cells, OM-10.1 cells (illustrated in Fig. 2B) were stimulated with SAHA, TNF-α, or prostratin in the presence of ARVs and either DMSO or 10 nM dCA (Fig. 5A). Similarly, J-Lat cells were activated in the presence of DMSO or dCA at 100 nM (Fig. 5B and C). Viral reactivation by all stimulators was potently blocked when dCA was present, by 78 to 97% in OM-10.1 cells (Fig. 5A), 74 to 78% in J-Lat clone 10.6 cells (Fig. 5B), and 88 to 90% in J-Lat clone 6.3 cells (Fig. 5C). Together, our results demonstrate that dCA inhibits viral transcription from several cell line models of latency by establishing a long-lasting state of latency refractory to viral reactivation by standard latency-reversing agents (LRAs; HDAC inhibitors, PKC activators, and cytokines).

Latent cell lines containing Tat/TAR-deficient proviruses are insensitive to dCA. To confirm that dCA inhibits HIV-1 transcription in a Tat-dependent manner, we took advantage of the ACH-2 (T-lymphocyte) (71, 72) and U1 (promonocyte) (73) cell lines that contain proviruses that are, respectively, TAR or Tat deficient. The provirus in ACH-2 cell lines contains a C37T point mutation in TAR that renders the provirus insensitive to Tat activation (74, 75). U1 cells carry two proviruses, with suboptimal levels of Tat activity; one lacks the Tat ATG initiation codon, and the other contains an H13L mutation in Tat that impairs the recruitment of P-TEFb (74, 76, 77). The Tat/TAR deficiency in these cell lines is responsible for their latent phenotype, which manifests as a predominance of nonproliferative viral transcripts (78, 79). In these Tat/TAR-restricted environments, dCA had no effect on viral mRNA production and only a modest impact on p24 production in ACH-2 and U1 cell lines treated for 33 and 38 days, respectively (Fig. 6A and B). As with other cell lines, no dCA toxicity or cytotastic effects were detected (see Fig. S6 in the supplemental material).

ACH-2 and U1 were then grown for 15 days in the presence of ARVs and DMSO or 10 nM dCA and stimulated with SAHA, prostratin, or TNF-α at days 9 and 15, followed by quantification of p24 antigen in supernatants (Fig. 6C and D). As expected, the reactivation of ACH-2 or U1 cells by all activators was only very modestly inhibited by dCA (between 21 and 44% reduction) (Fig. 6C and D). The origin of the small effect of dCA on the U1 cell line may be explained by the inhibition of the residual transcriptional activity of the mutated Tat, which still possesses an intact basic domain, the binding site for dCA (48). Moreover, in both U1 and ACH-2 cells, dCA may inhibit other functions of Tat that enhance HIV transcription, such as the recruitment by Tat of chromatin remodeling factors, e.g., SWI/SNF, an interaction mediated by the acetylated lysine 50 at the Tat basic domain (36, 37, 39). Finally, it cannot be ruled out that dCA may have Tat/TAR-independent effects. However, we previously demonstrated via an LTR reporter assay that, in the absence of Tat, dCA does not interfere with basal transcription nor with the activation pathway mediated by NF-κB when stimulated with TNF-α or PMA (48).

Overall, our results demonstrate that dCA can block viral reactivation from latently infected cells with competent Tat/TAR activity and has only limited activity when the Tat feedback loop is impaired.

dCA treatment limits viral rebound and reactivation in expanded primary CD4+ T cells derived from infected individuals. In Fig. 1, we show that viral rebound after antigenic stimulation was reduced by dCA treatment ex vivo of primary CD4+ T cells. In order to test the hypothesis that dCA treatment can prevent viral rebound upon ART termination in primary cells, we used in vitro-expanded primary CD4+ T cells from virally suppressed HIV-infected individuals. CD4+ T cells were initially expanded from two subjects (subjects A and B in Fig. 1) in the presence of IL-2, phytohemagglutinin (PHA), “feeder cells,” or with ARVs alone or ARVs together with dCA. From day 7 on, CD4+ T cells were cultured in the presence of IL-2 and ARVs or with ARVs and dCA (Fig. 7A), and viral production was monitored by an ultrasensitive RT-qPCR every 7 days. In the expanded cells model,
viral production usually decreased to low or undetectable levels by day 22 (see Fig. S7A in the supplemental material). To measure HIV rebound after treatment interruption in vitro, cells were washed at day 22 and kept with or without ARVs, in the presence of absence of dCA. Viral genomic RNA in the supernatant was measured 6 days later. In the presence of ARVs with or without ARVs, viral production was analyzed and is presented as described for panel A, as means of two independent activation experiments (n = 4). Percentages represent the percent inhibition. The two-tailed paired t test was used for statistical comparisons. ND, not detectable.

Collectively, our results show that a long-term in vitro treatment of primary CD4+ T cells with the Tat inhibitor dCA establishes a state of latency that renders the provirus almost incapable of reactivation. Thus, treatment with dCA establishes a state of transcriptional repression resulting in potent abrogation of viral reactivation from latency, even when drugs are withdrawn, implicating long-lasting repression of HIV promoter activity.

**DISCUSSION**

Our findings provide a proof of concept that a small-molecule Tat inhibitor, such as dCA, can potently inhibit residual HIV-1 levels of viral transcription in latently infected cells and block events of
FIG 6 dCA does not affect HIV-1 transcription in the ACH-2 or U1 models of HIV latency. (A and B) ACH-2 and U1 cells were infected with a virus with a mutant TAR or Tat, respectively (left panels). To analyze the effect of dCA on viral production in ACH-2 and U1 cells, cells were split and treated every 3 days on average with or without 10 nM dCA. Capsid production was quantified in a p24 ELISA. Data were normalized for each point to results with the DMSO control (as 100%) and are presented as means ± SD of three independent experiments. For analysis of the effects of dCA and time, a two-way repeated-measures ANOVA was performed. For ACH-2 cells (A), significant effects of dCA treatment (**, P = 0.0037) and time (***, P < 0.0002) are shown. For U1 cells (B), significant effects of dCA treatment (**, P = 0.0065) are shown. After post hoc Bonferroni correction (n = 3 per group), the statistical significance of results is indicated as follows: NS, nonsignificant; *, P < 0.05; **, P < 0.01; ***, P < 0.001; ****, P < 0.0001 (right panels). dCA does not inhibit viral transcription in ACH-2 or U1 cells. On the indicated day, viral mRNA was extracted and analyzed by RT-qPCR using Gag-Pol primers. RT-qPCR data are presented as means ± SD and are representative of at least two independent experiments. (C and D) dCA does not inhibit viral reactivation in ACH-2 or U1 cells. Cells were grown for 15 days with ARVs and in the presence or absence of dCA at 10 nM. At days 9 and 15, DMSO-treated (blue) or dCA-treated (red) cells and also treated with ARVs were representative of at least two independent experiments. (C and D) dCA does not inhibit viral reactivation in ACH-2 or U1 cells. Cells were grown for 15 days with ARVs and in the presence or absence of dCA at 10 nM. At days 9 and 15, DMSO-treated (blue) or dCA-treated (red) cells and also treated with ARVs were activated with SAHA, TNF-α, or prostratin for 24 h in the presence or absence of 100 nM dCA. Supernatant was collected at the end of the activation period and analyzed in a p24 ELISA. Data are presented as means ± SD of two independent activation experiments performed at days 9 and 15 (n = 4) except for U1 cells (SAHA and prostratin treatments, for which n = 2, due to the use of a different activation protocol at day 9). Percentages indicate the percent inhibition. The two-tailed paired t test was used for statistical comparisons. ND, not detectable.

viral reactivation. We have shown in several latently infected cell lines (Fig. 2), as well as in primary cells derived from HIV-infected individuals (Fig. 7), that dCA establishes a state of latency with an extremely impaired ability to reactivate. This state is characterized by a significant inhibition of an already low level of residual transcription, which results in a marked reduction in viral mRNA levels. Furthermore, given the transcription-repressed nature of the promoter following dCA treatment, viral reactivation becomes extremely inefficient (Fig. 4 and 5). Indeed, in latently infected primary CD4+ T cells isolated from nine HIV-infected subjects on suppressive ART, dCA reduced an average of 92.3% of the robust viral reactivation initiated by anti-CD3/CD28 stimulation (Fig. 1). We speculate that weaker stimulation of the type that latently infected cells would encounter in vivo would be inhibited to a greater extent by dCA.

Given the difficulty to perform biochemical studies with primary cells, especially when the ratio of latently infected cells is approximately 1 per 10⁶ uninfected cells (6), we do not yet have direct evidence that the promoter upon dCA exposure is epigenetically repressed. However, because of the different lines of evidence, such as the lack of RNAP II recruitment to the HIV promoter and ORF (Fig. 3), lack of viral rebound upon dCA discontinuation (Fig. 2A), and blocked reactivation (Fig. 1, 4, 5, and 7), it appears that access to the promoter is altered, implicating epigenetic modifications. There are two possible mechanisms by which dCA exerts its effect: (i) dCA simply accelerates the establishment of typical proviral latency by facilitating the corresponding epigenetic modifications; (ii) because dCA blocks a subset of the multiple Tat activities, it may result in unique epigenetic changes. For example, dCA may block binding of Tat to SWI/SNF (36), p300 (43), or C/EBP (80), dependent on Tat’s basic domain, but not P-TEFB (18), hGCN5 (41), PP1 (81), or DNA-PK (82), which bind to other regions of Tat and are all involved in chromatin remodeling or transcriptional activity. In future studies it will be important to describe which of these possibilities accounts for dCA’s suppression of reactivation.

HIV-1 lacking Tat undergoes some basal transcription, but it does not sustain a spreading infection (83). Early studies have shown that Tat-deficient mutants are frequently observed in peripheral blood mononuclear cells (PBMCs) isolated from infected
A Tat Inhibitor Blocks Latent HIV Reactivation

Individuals (84, 85) and that latently infected CD4+ T cells from subjects on ART are enriched for HIV-1 variants with impaired Tat activity (46). It has been speculated that a cause for entrance into latency results from low levels of P-TEFb and the presence of Tat mutants that still retain partial transcriptional activity to various extents, and therefore could be subject to stochastic reactivation (77). Moreover, an in vitro study showed that infected Jurkat cells overexpressing wild-type Tat had significantly fewer latent proviruses than regular infected Jurkat cells (86). Finally, a recent and very elegant study demonstrated that the Tat feedback loop is necessary preventing additional rounds of infection by maintaining latency. Limitations of current primary cell models of latency include the use of clonal HIV laboratory strains (59, 60), reliance on different cytokine cocktails to drive cells into latency, or use of transduction vectors (55). Here, we used expanded primary CD4+ T cells from HIV-infected subjects carrying autologous virus, which returns to a resting state after 3 weeks in culture (Fig. 7). In this model, cells spontaneously stop producing HIV particles but can be reinduced to produce virus after stimulation. Using this system, we confirmed our results obtained with primary CD4+ T cells from virally suppressed individuals (Fig. 1) and extended the results to show that dCA blocks viral reactivation with the PKC activator prostratin (Fig. 7). Most importantly, this system allowed us to demonstrate that dCA can block or at least significantly delay viral rebound upon ART discontinuation. These results suggest that a different set of epigenetic modifications is established at the HIV promoter when dCA promotes latency.

The most commonly explored strategy for HIV eradication is dubbed “kick and kill,” which attempts to purge the viral reservoirs by using LRAs such as HDAC inhibitors, while simultaneously preventing additional rounds of infection by maintaining ART (87, 88). This approach is based on the assumption that reactivation will prompt elimination of infected cells by cytotoxic effects and/or lysis mediated by HIV-1-specific cytolytic T lymphocytes (89). Despite an initial success using the HDAC inhibitor SAHA to reactivate the virus in several patients, the size of the viral reservoir was unchanged (87, 90). Moreover, a recent study demonstrated that the barrier to cure has increased, as the latent reservoir size is believed to be 60-fold larger than previously estimated from the results of a viral outgrowth assay (35). Given the stochastic nature of latent provirus reactivation, multiple activations will be required without the assurance of complete

FIG 7 dCA maintains a state of latency and blocks reactivation in primary expanded CD4+ T cells. (A) Schematic of generation of expanded CD4+ T cells and reactivation. CD4+ T cells were sorted from patient PBMCs and initially expanded with 1 µg/ml PHA, 100 U/ml IL-2, and irradiated autologous feeder PBMCs. Cells were then grown for 22 days in the presence of IL-2 and either ARVs alone or ARVs plus 100 nM dCA. At day 22, cells were split into 6 groups and either stimulated with prostratin or nonstimulated, with treatment stopped (TS) or continued for an additional 6 days before measuring HIV RNA viral production. Cells were then grown for 22 days in the presence of IL-2 and either ARVs alone or ARVs plus 100 nM dCA. At day 22, the ARVs or ARVs plus dCA cultured CD4+ T cells were washed, and all drugs were removed. Particle-associated HIV genomic RNAs were quantified by RT-qPCR at day 6 after TS (day 28). (C) Inhibition of viral reactivation upon prostratin stimulation in primary CD4+ T cells expanded in the presence of dCA. At day 22, the ARVs or ARVs plus dCA cultured CD4+ T cells were stimulated with prostratin or left unstimulated. Quantification was done as described for panel B (day 28). ND, nondetected. Data are presented as means ± standard errors of the means (n = 2).

reactivation of the latent reservoir, a prerequisite to a sterilizing cure.

Our results highlight an alternative approach to the “kick and kill” strategy. In this model (Fig. 8), a Tat inhibitor blocks the Tat feedback loop that is initiated after low-level basal reactivation and drives the viral promoter into more complete transcriptional inhibition. dCA treatment combined with ART would delay or halt viral replication, reactivation, and replenishment of the latent viral reservoir. Thus, the latent pool of cells in an infected individual would be stabilized, and death of the long-lived infected memory T cells could result in a continuous decay of this pool over time, possibly culminating in a sterilizing cure. It was previously demonstrated that the decay of the viral reservoir in patients with no “blips,” or episodes of clinically detectable viremia, was faster than in patients with blips (6, 91). These results argue that reducing low-level viremia and replenishment may reduce the half-life of the viral reservoir and reinforce the rationale for the inclusion of a Tat inhibitor in eradication strategies.

MATERIALS AND METHODS

Cell lines and culture. HeLa-CD4 cells were provided by Uriel Hazan (Université de Cachan, France). The population of latently infected HeLa-CD4 cells was obtained by infecting naive cells with NL4-3 virus and passaging cells until residual p24 production was observed (<500 pg/ml). The following reagents were obtained through the NIH AIDS Reagent Program, Division of AIDS, NIAID, NIH: efavirenz, zidovudine, raltegravir, and lamivudine. OM-10.1 cells (59) were obtained from Salvatore Butera, ACH-2 cells (71, 72) and U1 cells (73) came from Thomas Folks, and J-Lat full-length clones (6, 3 and 10.6) (60) were obtained from Eric Verdin. HeLa-CD4 cells were cultured in Dulbecco’s modified Eagle’s medium supplemented with 5% fetal bovine serum (FBS) and PEG (penicillin [100 units/ml], streptomycin [100 µg/ml], and l-glutamine [2 mM]). OM-10.1, U1, ACH-2, and J-Lat clones are cultured in Roswell Park Memorial Institute 1640 medium with 10% FBS and PEG. All cells were cultured at 37°C and 5% CO₂.

Passaging of latently infected cells. Latently infected HeLa-CD4 cells were seeded at 1 x 10^6 cells per 10-cm² dish culture dish. OM-10.1, ACH-2, and U1 cells were seeded at 1 x 10^6 to 2.5 x 10^6 cells/ml, and J-Lat clones were seeded at 5 x 10^5 cells/ml. All cells were passaged every 3 days on average at the indicated concentrations of dCA or DMSO. OM-10.1, ACH-2, and U1 were grown also in the presence of ARVs (200 nM lamivudine, 200 nM raltegravir, 100 nM efavirenz) (Fig. 2B, 5A, and D). Latent viral reactivation. Latently infected HeLa-CD4 cells were treated with PMA (20 nM) and iono (2 µM) for 24 h with 10 nM dCA or DMSO. ACH-2 and U1 were cultured for 15 days in the presence of ARVs and in the presence or absence of dCA at 10 nM (Fig. 6C and D). At days 9 and 15, ACH-2 cells (5 x 10^6 cells/ml) were activated for 24 h with SAHA (1 µM) or TNF-α (10 ng/ml) or for 9 h with prostratin (5 µM) in 100 nM dCA or DMSO. U1 cells were grown and activated similarly, with SAHA (2.5 µM), TNF-α (10 ng/ml), or prostratin (1 µM) for 24 h. OM-10.1 cells were grown and activated similarly at days 219 and 226 (Fig. 5A). At day 0, J-Lat cells (5 x 10^5 cells/ml) were activated with SAHA (1 µM), TNF-α (10 ng/ml), or prostratin (1 µM) for 24 h (Fig. 5B and C). p24 production in the supernatant was determined in an ELISA.

Western blot analysis. Original uninfected HeLa-CD4 cells and latently infected HeLa-CD4 cells (treated either with DMSO or 10 nM dCA) were activated or not with PMA (20 nM) and iono (2 µM) for 30 min. Cells were lysed (lysis buffer of 20 mM HEPEs [pH 8.0], 100 mM KCl, 0.2 mM EDTA, 5 mM β-mercaptoethanol, 0.1% IGEPAL CA-630, 10% glycerol, 10 mM sodium fluoride, 1 mM sodium orthovanadate, and Complete EDTA-free protease inhibitor cocktail [Roche]), and the lysate was centrifuged at 18,000 x g for 10 min at 4°C. The protein concentration in the supernatant was quantified with the Bio-Rad protein assay (catalog number 500-0006). Total protein extracts were separated by SDS-PAGE and transferred onto polyvinylidene difluoride membranes. Membranes were probed with an anti-β-actin mouse monoclonal antibody (MAB) from Sigma (catalog number A5441) or MEK1/2 rabbit polyclonal Ab (9122), phospho-MEK1/2 (Ser217/221) rabbit polyclonal Ab (9121), p44/42 mitogen-activated protein kinase (MAPK; ERK1/2) mouse MAb (9107), or phospho-p44/42 MAPK (ERK1/2; Thr202/Tyr204) rabbit MAB (4370) from Cell Signaling. The membranes were incubated in horseradish peroxidase-conjugated anti-mouse or anti-rabbit IgG goat polyclonal antibodies as secondary antibodies. Bands were visualized by using the enhanced chemiluminescence Western blotting system (Amersham).

Tat transfection. pGL4.74-Tat(101)-F-wt expressing Flag-tagged 101-amino-acid Tat was generated by PCR as previously described (48).
To reactivate the latent virus in HeLa-CD4 cells, 1 × 10^6 cells were seeded and transfected 24 h later with 5 μg of pGL4.74-Tat(101)-F-wt or the empty vector control in the presence or absence of 10 nM dCA. Viral production in the supernatant was quantified every 3 days via a p24 ELISA.

p24 ELISA. Quantification of HIV p24 capsid production was performed using the antigen capture assay kit from Advanced BioScience Laboratories, Inc. (catalog number 5447), according to the manufacturer’s protocol.

RT-qPCR analysis of cell-associated RNA. Total RNA was prepared using the RNasey kit (Qiagen). First-strand cDNA was prepared from total RNA with oligo(dT) using a SuperScript III kit (Invitrogen). RT-qPCR was performed with the cDNA, using a LightCycler 480 SYBR Green 1 Master system (Roche). Analyses were performed in triplicate, and the mean RNA expression levels were normalized to viral mRNA expression of glyceraldehyde-3-phosphate dehydrogenase (GAPDH). All reactions had a negative control in which no reverse transcriptase was added. The GAPDH reference gene was amplified using the primers 5′-GAPDH/3′-GAPDH. NL4-3 amplification (Vpr) was performed using the primers P10/P11 (see Table S1 in the supplemental material). OM-10.1, U1, ACH-2, and J-Lat clone cDNA analyses were performed using the primers GAPPol-For/GAPPol-Rev (see Table S1). IL-1β mRNA analysis was performed using the primers IL-1β-For/IL-1β-Rev (see Table S1).

Quantification of integration events. Genomic DNA (gDNA) was prepared from 2 × 10^6 HeLa-CD4 or OM-10.1 cells by using the DNeasy blood and tissue kit (Qiagen). Integration events were quantified by Alu-Gag PCR (Alu/P9) for HeLa-CD4 cells or Alu/GagPol-Rev cells for OM-10.1, followed by nested qPCR with P6/P8 or GagPol-For/GagPol-Rev, respectively (see Table S1 in the supplemental material). The cycling conditions for the Alu-PCR included an initial denaturation (94°C for 2 min), followed by 20 cycles of amplification (94°C for 20 s, 55°C for 10 s, and 72°C for 1 min) and a final elongation step (72°C for 10 min) and using the primers B1/B4. Triplicates were pooled. A nested PCR in triplicate to amplify individually each Cpg was performed using the same cycling conditions and the primers B1/B2 (Cpg1) and B3/B4 (Cpg2) (see Table S1 in the supplemental material). Resulting single-banded PCR products of each triplicate sample were pooled and TOPO cloned using the TOPO TA cloning kit (Invitrogen). Nine clones for each condition were submitted for sequencing using standard M13F and M13R primers (Operon). Only PCR clones with at least 95% conversion of cytosines outside Cpgs were taken into account.

HIV-infected subjects. Nine HIV-seropositive patients on stable suppressive ART for at least 3 years were enrolled in this study. All subjects signed informed consent forms approved by the Oregon Health and Science University and the Martin Memorial Health Systems (Stuart, FL) or by the Royal Victoria Hospital and the CR-CHUM Hospital (Montreal, Quebec, Canada) review boards. All patients underwent leukapheresis to collect large numbers of PBMCs.

Viral reactivation from CD4+ T cells isolated from virally suppressed subjects. In an effort to assess the effect of dCA on latency, we selected patient samples with CD4+ T cells that did not display detectable levels of spontaneous viral production when cultured in vitro but which robustly released virus upon antigen stimulation. Total CD4+ T cells were isolated from PBMCs of nine virally suppressed subjects by using magnetic bead-based negative selection (StemCell Technologies). Isolated CD4+ T cells (5 × 10^6 cells per well) were cultured in the presence of ARVs (100 nM efavirenz, 180 nM zidovudine, 200 nM raltegravir). Cells were stimulated with Dynabeads human T-expander CD3/CD28 (Invitrogen) at a concentration of one bead per cell in the presence or absence of dCA (100 nM). Medium was harvested every 3 days for quantification of viral particles and replaced with fresh medium containing ARVs and dCA when appropriate. Freshly collected cell culture supernatants were centrifuged for 1 h at 25,000 × g to pellet HIV particles. Viral RNA at day 6 was extracted using the Qiamp viral RNA kit (Qiagen) and quantified using an ultrasensitive seminested real-time RT-qPCR with a detection limit of a single copy of HIV RNA. Extracted viral RNA was reverse transcribed and subjected to 16 cycles of amplification with the primers O1/O2. Preamplified products were diluted and subjected to a nested real-time PCR for 40 cycles on a Rotor-Gene Q apparatus and using the primers O3/O4 and H11001/H11002 (see Table S1 in the supplemental material). In all experiments, serial dilutions of HIV particles (LAI strain) in culture medium were processed in parallel with experimental samples. A paired Student’s t test was performed to test for statistical significance (Fig. 1).

Generation of expanded CD4+ T cells from subjects A and B. We expanded primary CD4+ T cells from two successfully treated donors, subjects A and B (Fig. 1) after at least 3 years on ART. For that, 50 × 10^6 PBMCs previously collected were thawed, and sorted CD4+ T cells were initially expanded with 1 μg/ml of PHA, 100 μM of IL-2, irradiated feeder PBMCs, and either ARVs alone or ARVs plus 100 nM dCA in medium supplemented with human serum for 22 days. After 7 days, the cells were cultured only with IL-2 and the indicated drugs. At day 22, CD4+ T cells were split into 6 groups for 6 different conditions and either...
stymulated with 1 μM prostratin or nonstimulated, treatment stopped (TS), or continued for an additional 6 days before measuring HIV RNA viral production by ultrasensitive RT-qPCR in the supernatant. Cell viability was monitored weekly using trypan blue dye exclusion staining.

**Statistical analysis.** Statistics were performed with GraphPad Prism, and a P value of ≤0.05 was considered significant for all comparisons. The two-tailed paired Student’s t test was used when applicable. In Fig. 2D and 6A and B, data were normalized for each point to 100% of the DMSO control and are reported as the means ± standard deviations (SD) of three independent experiments (n = 3). Comparisons between data from vehicle- and dCA-treated cell lines were performed using a two-way analysis of variance (ANOVA) repeated-measures test. The Bonferroni correction was used for post hoc analysis.
